Outline

Profiling the deviance

Plotting the profiled deviance

Profile pairs

Profiling models with fixed-effects for covariates

Likelihood ratio tests and deviance

- ▶ In section 2 we described the use of likelihood ratio tests (LRTs) to compare a reduced model (say, one that omits a random-effects term) to the full model.
- ► The test statistic in an LRT is the change in the deviance, which is negative twice the log-likelihood.
- ► We always use maximum likelihood fits (i.e. REML=FALSE) to evaluate the deviance.
- In general we calculate p-values for a LRT from a χ^2 distribution with degrees of freedom equal to the difference in the number of parameters in the models.
- ► The important thing to note is that a likelihood ratio test is based on fitting the model under each set of conditions.

Profiling the deviance versus one parameter

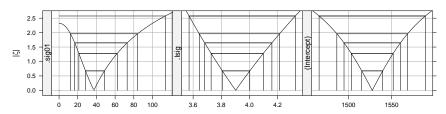

- ▶ There is a close relationship between confidence intervals and hypothesis tests on a single parameter. When, e.g. $H_0: \beta_1 = \beta_{1,0} \text{ versus } H_a: \beta_1 \neq \beta_{1,0} \text{ is not rejected at level } \alpha \text{ then } \beta_{1,0} \text{ is in a } 1-\alpha \text{ confidence interval on the parameter } \beta_1.$
- ► For linear fixed-effects models it is possible to determine the change in the deviance from fitting the full model only. For mixed-effects models we need to fit the full model and all the reduced models to perform the LRTs.
- ▶ In practice we fit some of them and use interpolation. The profile function evaluates such a "profile" of the change in the deviance versus each of the parameters in the model.

Transforming the LRT statistic

- ▶ The LRT statistic for a test of a fixed value of a single parameter would have a χ^2_1 distribution, which is the square of a standard normal.
- ▶ If a symmetric confidence interval were appropriate for the parameter, the LRT statistic would be quadratic with respect to the parameter.
- ▶ We plot the square root of the LRT statistic because it is easier to assess whether the plot looks like a straight line than it is to assess if it looks like a quadratic.
- ➤ To accentuate the straight line behavior we use the signed square root transformation which returns the negative square root to the left of the estimate and the positive square root to the right.
- ▶ This quantity can be compared to a standard normal. We write it as ζ

Evaluating and plotting the profile

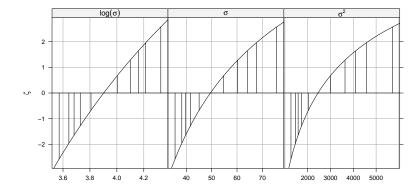

▶ The parameters are σ_b , $\log(\sigma)$ (σ is the residual standard deviation) and μ . The vertical lines delimit 50%, 80%, 90%, 95% and 99% confidence intervals.

Interpreting the univariate plots

- A univariate profile ζ plot is read like a normal probability plot
 - ▶ a sigmoidal (elongated "S"-shaped) pattern like that for the (Intercept) parameter indicates overdispersion relative to the normal distribution.
 - ▶ a bending pattern, usually flattening to the right of the estimate, indicates skewness of the estimator and warns us that the confidence intervals will be asymmetric
 - ▶ a straight line indicates that the confidence intervals based on the quantiles of the standard normal distribution are suitable
- Note that the only parameter providing a more-or-less straight line is σ and this plot is on the scale of $\log(\sigma)$ not σ or, even worse, σ^2 .
- We should expect confidence intervals on σ^2 to be asymmetric. In the simplest case of a variance estimate from an i.i.d. normal sample the confidence interval is derived from quantiles of a χ^2 distribution which is quite asymmetric.
- ► Yet many software packages provide standard errors of variance component estimates as if they were meaningful.

Profile ζ plots for $\log(\sigma)$, σ and σ^2

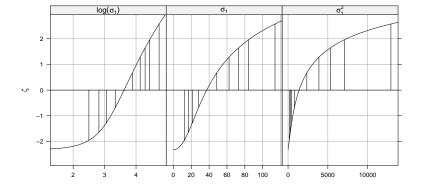

- ▶ We can see moderate asymmetry on the scale of σ and stronger asymmetry on the scale of σ^2 .
- ▶ The issue of which of the ML or REML estimates of σ^2 are closer to being unbiased is a red herring. σ^2 is not a sensible scale on which to evaluate the expected value of an estimator.

Profile pairs plots

- ► The information from the profile can be used to produce pairwise projections of likelihood contours. These correspond to pairwise joint confidence regions.
- ► Such a plot (next slide) can be somewhat confusing at first glance.
- ▶ Concentrate initially on the panels above the diagonal where the axes are the parameters in the scale shown in the diagonal panels. The contours correspond to 50%, 80%, 90%, 95% and 99% pairwise confidence regions.
- ► The two lines in each panel are "profile traces", which are the conditional estimate of one parameter given a value of the other.
- ▶ The actual interpolation of the contours is performed on the ζ scale which is shown in the panels below the diagonal.

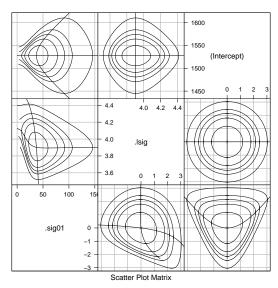

Profile ζ plots for $\log(\sigma_1)$, σ_1 and σ_1^2

- ▶ For σ_1 the situation is more complicated because 0 is within the range of reasonable values. The profile flattens as $\sigma \to 0$ which means that intervals on $\log(\sigma)$ are unbounded.
- lacktriangle Obviously the estimator of σ_1^2 is terribly skewed yet most software ignores this and provides standard errors on variance component estimates.

Profile pairs for model fm1

> splom(pr1)

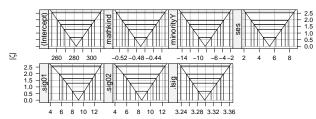

About those p-values

- ➤ Statisticians have been far too successful in propagating concepts of hypothesis testing and p-values, to the extent that quoting p-values is essentially a requirement for publication in some disciplines.
- ▶ When models were being fit by hand calculation it was important to use any trick we could come up with to simplify the calculation. Often the results were presented in terms of the simplified calculation without reference to the original idea of comparing models.
- ▶ We often still present model comparisons as properties of "terms" in the model without being explicit about the underlying comparison of models with the term and without the term.
- ▶ The approach I recommend for assessing the importance of particular terms in the fixed-effects part of the model is to fit with and without then use a likelihood ratio test (the anova function).

Profiling a model for the classroom data

```
> pr8 <- profile(fm8 <- lmer(mathgain ~ mathkind +
+ minority + ses + (1 | classid) + (1 | schoolid),
+ classroom, REML = FALSE))</pre>
```

- ▶ The fixed-effects coefficient estimates (top row) have good normal approximations (i.e. a 95% confidence intervals will be closely approximated by estimate \pm 1.96 \times standard error).
- ▶ The estimators of σ_1 , σ_2 and $\log(\sigma)$ are also well approximated by a normal. If anything, the estimators of σ_1 and σ_2 are skewed to the left rather than skewed to the right.

Hypothesis tests versus confidence intervals

- As mentioned earlier, hypothesis tests and confidence intervals are two sides of the same coin.
- ► For a categorical covariate, it often makes sense to ask "Is there a signficant effect for this factor?" which we could answer with a p-value. We may, in addition, want to know how large the effect is and how precisely we have estimated it, i.e. a confidence interval.
- ► For a continuous covariate we generally want to know the coefficient estimate and its precision (i.e. a confidence interval) in preference to a p-value for a hypothesis test.
- ▶ When we have many observations and only a moderate number of fixed and random effects, the distribution of the fixed-effects coefficients' estimators is well-approximated by a multivariate normal derived from the estimates, their standard errors and correlations.
- With comparatively few observations it is worthwhile using profiling to check on the sensistivity of the fit to the values of the coefficients.

Profile pairs for many parameters
